30 April 2012

Abstract

The modern day smart phone processor is quickly approaching clock speeds of up to 2GHz while possessing up to 1Gb of RAM. By contrast, the Apollo Guidance Computer from the 1960s which had put man on the moon had a clock speed of a 2.048MHz and 2048 words of RAM [9]. The average person possesses in his/her pocket more processing power than all but the more recent computer desktops built within the past ten years or so. And while optical music recognition has been around since 1966 [2], it has never been able to take advantage of the massive technological resource that resides within the current smartphone. This project aims to develop an application within the iOS mobile operating system to convert written data on a sheet of music into digital data which may be interpreted and played by a computer or piano-playing robot. Computer vision is utilized to process the image and do the recognition process.

Procedure

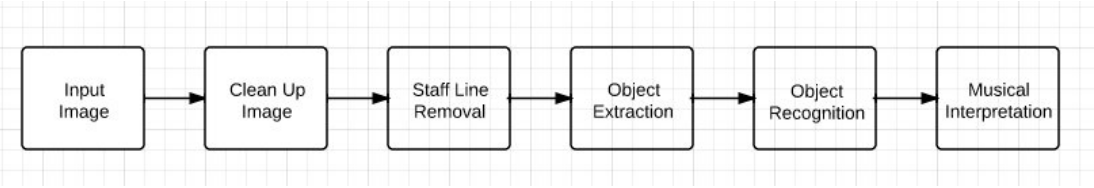

Figure 1: The flow chart shows graphically the process of optical music recognition. The image must go through these steps in order to be fully processed and yield meaningful results.

Almost all forms of optical music recognition since its inception follow the same general structure when it comes to realizing the objective. In short, optical

music recognition must have the following to be considered optical music recognition: Staff line detection and removal, musical object extraction, musical object classification or recognition, and musical object interpretation.

Staff Line Detection

A staff is a set of five horizontal lines which determine the pitch of a note on the sheet music. These lines cover the majority of the sheet music and are absolutely crucial to the interpretation of music. However, staff lines pose a problem to OMR systems because they connect and overlap with almost all the musical objects on a given sheet of music. Therefore to simplify the recognition process the staff lines need to be recognized and removed. To realize this task, the OMR system creates a histogram of the number of black pixels which exist in any given row. Because staff lines are always horizontal (given a perfect image), the locations of staff lines are always given by the highest peaks of the histogram.

It would then seem fairly trivial to simply remove the staff lines after discovering their locations, however this would separate objects into many different pieces and cause far too much segmentation and create many avoidable problems. An algorithm that properly removes the staff lines would scan across the rows of the staff lines, removing the existing black pixel if there are no black pixels above nor below it. The reasoning behind this is that if a specific point has a black pixel either above or below it, it likely is part of a bigger symbol. However, if a specific point does not have a black pixel surrounding it, it can be assumed to just be part of the staff line in empty space.

Figure 2: The histogram of black pixels is shown in red. Note that the highest peaks of the histogram correspond to the location of the staff lines and show where the staff lines need to be removed.

Musical Object Extraction

With the staff lines removed, the image then becomes a collection of disconnected symbols and objects. A flood fill algorithm, much like the popular paint bucket function present in most graphic editing software, could then be utilized to extract each object. Every time the algorithm comes across a black pixel, it will run the flood fill algorithm on that specific object, which will cause that object to become white. This algorithm will save the shape of an object as well as the location of the object. The entire extraction process produces a large linked list with all the necessary data needed for the rest of the recognition process. By this step, the sheet music has been completely processed and the result is a large collection of data in form of objects that need to be identified and given meaning.

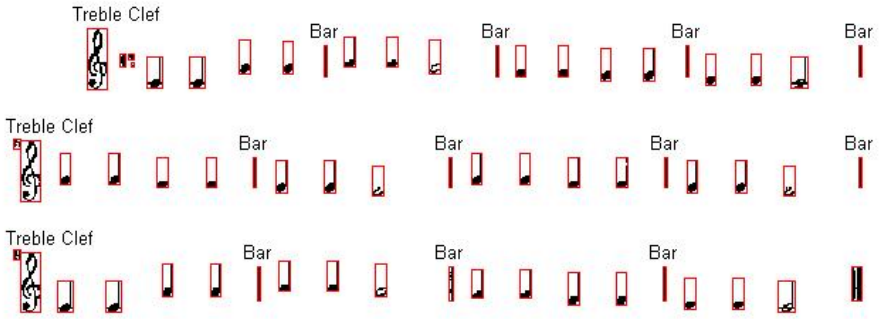

Figure 3: With the staff line removed, the flood fill algorithm is then applied to every object within the page to extract data from each individual object. The flood fill algorithm works by taking one seed pixel and moving away from that seed until it detects the border of the object, then filling everything inside the border with another color. The data is then processed in the next step of the OMR system.

Musical Object Classification

The classification and recognition process makes up the bulk of the OMR system. Certain objects such as the treble clef and bar lines may be recognized simply by normalizing the object with the height of the staff lines and finding the size of the object or by the ratio of its height versus its width. This takes advantage of their unique shapes and is illustrated by Figure 2. However most objects require much more advanced methods to be correctly and confidently classified. Two methods were tested and tried throughout the course of the project.

Correlation

Template matching was utilized by following the method of calculating correlation between a model and the image as shown in [5]. A correlation is defined by the sum of the product of the image pixel values and the model pixel value. If the correlation is high then the model and the image must be very similar. However this method is heavily dependant on scale and so a SURF method was adopted to take advantage of its scale-invariant and rotation-invariant properties so that a more robust and flexible system could be implemented.

SURF

OpenCV's implementation of SURF was utilized. SURF (Speeded Up Robust Features) is an algorithm that creates descriptor vectors by finding the most prominent features of an image and comparing that vector with another via Euclidean distance to see how well they match together. The OpenCV function *cvExtractSURF* automatically extracts good features for this implementation, and *findNaiveNearestNeighbor* can be used as a crude way to measure the Euclidean distance between two features which are being compared. The full intricacies of the code can be seen in the appendix, but the general gist is that OpenCV automatically generates the features we need for the comparisons, and then finding the minimum squared distance between two vectors will lead to determining whether or not the features match up well or not.

Note in Figure 2 that on the upper left portion of the image the *Common Time Signature*has been segmented into three different objects. A technique has been utilized from Bainbridge *et al* [1] regarding this issue and essentially the bounding regions would be extended before template matching is performed.

Musical Object Interpretation

The word interpretation was found to be most fitting because after the OMR system has correctly classified all the objects, by itself it cannot understand how the piece flows together. The last step of OMR is for the system to understand how to play back all the objects it had separated and classified. This involves storing information such as note pitch and beat length within the notes and also checking to see if the number of beats in each individual measure of music adds up according to the time signature and more generally speaking that the rules of music writing are being followed. This step also functions as a way of verifying the results of the recognition process. There is a certain syntax that must be

followed when writing music and by recognizing this fact, the recognition rate may be increased by eliminating certain choices. The system, at this final stage of the OMR process, has processed the given input, extracted the meaningful objects, assigned a meaning to those objects, and is ready to play the recognized music.

Playback

Playback was originally realized by using the AVFoundation framework and AVAudioPlayer class within iOS to play the notes. A sound is specified and a play method is called to output the audio. This is a rather tedious method and does not offer a lot of flexibility in playback, but still served as a relatively easy to implement way to output audio. This method involves playing a sinusoid at certain frequencies which correspond to certain notes. Universally A4 (the A above middle C on the piano keyboard) is defined as 440.0 Hz, with A3 (the A which is located one octave below A4) being 220.0Hz, and so on and so forth. Every eight notes constitutes an octave, and each octave contains 12 semitones of equal size. With this information theoretically all the notes that can be played on the piano can be generated with some symbol algebra involving logarithmic functions, with some interpolations necessary to achieve more exact frequencies. AVAudioPlayer needed to have an audio file in the library already loaded before the method call is made, and the audio tones were all generated in MATLab (see appendix for code).

Frequency f of the nth key is given by: $f(n) = (440)(2^{\frac{n-49}{12}})$

However, the open source SoundBankPlayer (developed by Matthijs Hollemans and licensed under the terms MIT license) is a much more powerful class when it comes to musical playback. It allows for a full 88 note representation without needing 88 individual note files. The SoundBankPlayer can be seen as an middle step between AVAudioPlayer and the ideal playback module, allowing convenient playback.

Experimental Results

Figure 4 shows how the algorithm is negatively effected by low resolution images. Many sample music sheets had to be omitted throughout the development process because their low resolution were causing many problems that were solved upon finding higher quality images.

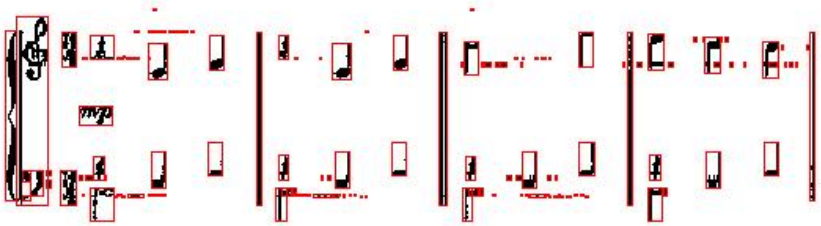

Figure 4: The resolution of the image is 533 x 136. The resolution of the previous images where the algorithms worked better was 912 x 391. When the input image resolution was too low many random artifacts tended to appear on the page and many symbols became skewed. It was experimentally determined that the target image should be at least 900 pixels wide and should not have too many objects on the page to avoid memory problems while still maintaining quality.

Discussion

Difficulties

While it may be rather juvenile, a rather legitimate source of frustration in the project involved learning to use a Macintosh computer. Much time was dedicated to wrestling with unresponsive controls, hotkeys that no longer worked, but most importantly with the development software, Xcode. To develop software for iOS, Apple requires all work to be done in Xcode, using the Objective-C language. The learning curve was rather steep and frustrating at times.

Converting the MATLab code to Objective-C proved to be a large obstacle. MATLab is able to easily deal with large matrices and computations between them, and so many functions and algorithms which were trivial to implement within MATLab did not transfer over easily and caused many deadlines to be missed and ultimately resulted in a considerable loss in efficacy. Moreover, Objective-C is not the ideal platform for image processing, as all the images are resized relative to the display and many outputs are distorted when working within Objective-C. Many features that can be used for image recognition are lost in this process.

Lastly, when dealing with high resolution pictures, there were many times when memory management was an unforeseen complication. This then caused certain code to be recoded and better written or for the pictures to be downsampled so the image sizes would be smaller, at the cost of losing quality and information.

Sources of Error

The project started under the assumption that the image to be read in was taken under ideal situations: a perfectly rectangular sheet scanned at 300 DPI with very high contrast and no extra noise. Yet reality is not so kind as to submit to our assumptions and thus our sources of error came from anything that deviated from our original assumption. If the paper was slightly rotated by even a few degrees, the staff line detection histogram would be completely useless. If the image had far too many shades of grey instead of binary black and white further issues would come up. If there were random specks in the paper they would be analysed, categorized, and add confusion to the outcome. The list goes on and on, but hope is not all lost. There are plans for future work and extensions which would provide solutions to these problems.

Future Work and Extension

Rectification

Since the project's beginning there had been plans of implementing computer vision in the form of image rectification in the project. The transformation required in rectification is obtained through 8 separate variables. These 8 variables can be obtained by 4 distinct points, which each contribute 2 variables. This was extremely easy to implement with MATLab functions *maketform* and *imtransform* (See appendix for code). Essentially the code is solving a system of eight linear equations to approximate eight values to get the transformation needed. This feature has not been implemented within the iOS application due to it being too time intensive to convert the code to Objective-C.

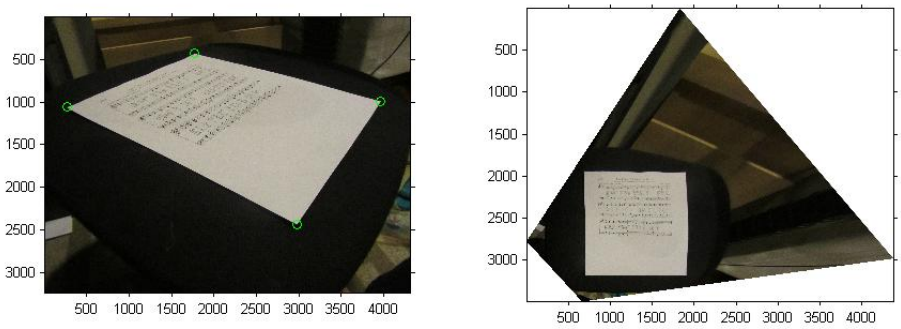

Figure 5: The four corners (selected in green) were chosen as points to estimate the homography. The result gives an image with the original sheet music, but now rendered horizontally and generally much more readable upon zooming in.

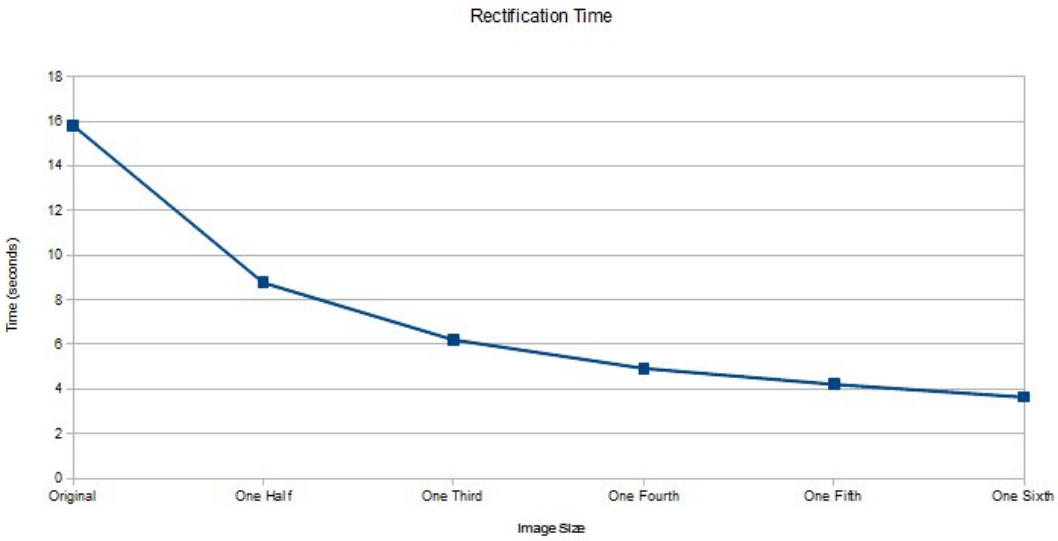

Figure 6: The performance of the rectification function, measured by how long the function took in seconds to run versus the size of the image. The original image size is 4320 x 3240, and subsequent downsampling does little to improve the efficiency of the algorithm after the fourth iteration, as it seems to converge to a value of approximately three seconds.

Refined Image Processing

There exist plans to improve the robustness of the program to combat the aforementioned sources of error. Care needs to be taken, as the smallest of specks can actually be a part of written music. For example, a small dot to the right of a note increases the note length by half the original value, whereas a small dot directly above or below the note actually decreases the note length, and a small dot could easily be mistaken as noise by most filtering processes. It seemed to make sense to include another image processing step after the recognition and analysis portion of the program has been fully realized, as it should be easier to distinguish between necessary and unnecessary information after the program can guess what should or should not exist in the page.

Editable Music

Lastly the project has an end goal of achieving an editable sheet of music. This feature deviates from the computer vision-centered focus of the project but is a necessary feature of any music software. One of the main advantages of digitizing music would be to be able to transpose the piece into a different key, as this is a highly tedious process that could be easily done by a computer. Moreover

being able to change parameters such as tempo and instrument voices will also be desirable features in any sort of musical application.

Synthesis Tool-kit for Playback

The playback portion of the project was originally planned to be realized by utilizing the Synthesis toolkit Instrument Network Interface (SKINI). SKINI was selected because it was designed to be MIDI compatible and accepts text as input, while fully allowing the usage of many different instruments with many easily variable parameters, such as dynamics and tempo.. The OMR application would generate as an output MIDI note numbers (a number between 0 - 127 which corresponds to a specific pitch), the note length (an eighth note, quarter note, half note, etc.), and a tempo (which is fixed at 96 beats per minute for simplicity's sake unless otherwise specified) which would all be accepted and outputted in any instrument and intensity desired. However, this feature did not manage to make it into the project time frame but is expected to be incorporated in the near future.

Current Trends in Robotics

Robotics has come a long way in the recent years. From commercial applications such as an automated mobile vacuum cleaner to industrial advances in manufacturing to even military usage, the rate of growth for robotics has been nothing short of amazing. Newer and newer technologies are always being tested and developed to further advance the field of robotics and computer vision.

An example of particularly impressive applications of robotics lies in the field of medical surgery . Minimally invasive surgery (MIS) is contrasted with open surgery, opting to insert instruments into the patient's body through a small incision to perform the necessary operation. The advantages of MIS include faster recovery, less physical trauma, more potential for teleoperation [4].

Surgeons are now able to utilize technology even more through the advances of robotics and computer vision to aid in their MIS operations. The Wireless Hands-Free Surgical Pointer (WHaSP) for MIS is a system developed which clearly demonstrates the usefulness of computer vision in the medical field.

During a minimally invasive surgical operation, both the surgeon instructor and the assistant trainee have to utilize both hands to operate surgical instruments. Furthermore, each person often has their own display monitor which displays vital information from their instruments during the surgery. If both surgeons were both experts, there would be no problem. However, for pedagogical purposes,

this is far from ideal. To aid in the training of MIS surgeons, the WHaSP system was developed as a way for the instructor to point to multiple video monitors without removing his/her hands from the instruments [8]. This system would need to combine and utilize data from the headset trackers and the displays used within the operating room to benefit the users. By tracking the headsets worn by the instructor surgeon, a new way is opened for training newer surgeons in the field of MIS.

In addition to research such as the WHaSP system, much work is being done for the tracking of intrabody instruments. Current methods such as optical tracking and electromagnetic tracking respectively require line of sight and lack of interference from the many metallic instruments within the operating room. Therefore an idea was proposed which would combine multiple sensors and data into one integrated tracking system to enhance the current method of intrabody instrument tracking [4].

As impressive as MIS is, it is not the end all be all of medical surgery advancement. MIS removes all hand eye coordination due to the surgeons no longer being able to see the physical points of contact and also the surgeons are deprived of force feedback from their instruments. To further complicate things, many instruments used in MIS have very limited degrees of freedom and range of motion due to how they have to fit through a very small incision to enter the body. To address this issue, researchers are working on designing miniature modular *in vivo* robots to increase the efficiency of MIS [7]. The complete system composes of three separate modules: a camera with 2 degrees of freedom (DoFs), a retraction robot with 2 DoFs, and a manipulator with 6 DoFs. While the modules themselves has not be fully manufactured, initial research shows that the theory behind this concept is sound and the camera which has been manufactured does indeed work as intended.

MIS suffers from another condition, but this condition is extremely common in the world. Surgeons working in MIS suffer fatigue, much like many other humans doing any sort of physical labor. Robotics replacing humans in doing repetitive manual tasks has been around as long as the concept of robotics has been, but to replace something as complicated as MIS is truly an impressive feat. By combining position and imaging, researchers are able to keep the error of a ceiling mounted robotic arm under 1.3mm [6]. This process of combining data and utilizing computer vision (including the manipulation of various rotational matrices) allows for up to four ceiling mounted mechanical arms to perform complicated processes in an automated fashion.

Lastly, exciting work is being done in the field of microsurgery, as well as the field of MIS. Microsurgery is simply defined as surgery requiring a microscope,

which in turn indicates a need for extreme precision. Some microsurgery operations requires manipulation of structures as small as 10 micrometers (such as the thin retinal internal limiting membrane), but normal human surgeons typically do not have precision needed, having involuntary hand motion that ranges to several hundred micrometers [3]. The Micron handset aims to improve precision by employing the same method of image stabilization in a camera and actuates its own tip to balance the involuntary human hand movements. This handset would be able to differentiate between the most minute hand movements and give unprecedented control to surgeons operating in delicate operations.

Medical practices has progressed so much in recent times directly due to the advances in robotics and computer vision. To think that there are currently devices that can help a surgeon manipulate the smallest of structures would simply be unfathomable even a few years ago. Without a doubt, robotics and computer vision will continue to augment the capabilities of our doctors and surgeons in the future, and contribute to the saving of countless lives.
